

IMPROVED HYBRID GENE LIBRARIES AND USES THEREOF

RELATED PATENT APPLICATION

5 This Patent Application is a Divisional of U.S.
Patent Application Serial No. 10/071,136, entitled
Improved Hybrid Gene Libraries and Uses Thereof, filed on
February 6, 2002, which claims priority to U.S.
Provisional Application No. 60/279,788, entitled *Cloning*
10 *Vector for Hybrid Gene Libraries*, filed March 29, 2001.

TECHNICAL FIELD

 This invention relates to the construction and use
of hybrid gene cDNA libraries.

BACKGROUND OF THE INVENTION

Complementary deoxyribonucleic acid, or cDNA libraries are collections of nucleotide sequences copied from messenger ribonucleic acid, or mRNA, isolated from specific organisms, tissues or cells. The usefulness of cDNA libraries stems from the fact that they ideally represent a collection of all, or at least most of, the mRNA molecules present in the starting material in a form that is more stable and easy to propagate than the mRNA itself. Hybrid gene libraries are a specific type in which the cDNAs are ligated into a cloning vector containing sequences encoding a peptide of defined composition, such that all cDNAs can be expressed in hybrid proteins in which the cDNA expression product is fused to the common peptide. This common peptide is the common peptide of the entire library. Hybrid gene libraries are especially useful for a variety of purposes:

Epitope or affinity tagging of gene products for detection / purification, if the common peptide is an epitope or affinity tag.

Subcellular targeting or secretion of library gene products, if the common peptide is a targeting or trafficking signal.

Tracer labeling of library gene products for detection, if the common peptide is a label traceable by luminescence, fluorescence or other methods.

Production of hybrid protein libraries for in vivo or in vitro screening, detection and quantitation of molecular interactions, using methods that may include yeast or

other one-, two- or three-hybrid methods, fluorescence
resonance energy transfer spectroscopy, affinity or
immunoaffinity binding and other methods, which is
referred to herein as "molecular interaction methods", if
5 the common peptide displays a biological activity
dependent on one or more molecular interaction(s).

Traditional methods that utilize hybrid gene
libraries for gene discovery are designed to yield
results in a linear, gene-by-gene fashion. Those methods
10 have been designed with the rationale that the discovery
of a previously unknown gene is the starting point for
research carried out by one or a few individuals. By
contrast, more modern high-throughput automated methods
allow the performance of certain assays at a scale
15 hundreds of times that of older procedures. These methods
permit, therefore, the performance of massive screens
aimed at saturation of the system under study. The aim of
modern high throughput gene screens is to discover all
the possible genes involved in a specific area; that is,
20 to "leave no stone unturned." As it pertains to cDNA
libraries, then, it becomes crucial to have total
representation of mRNAs.

As currently constructed, cDNA libraries rarely
achieve total representation, in large part because cDNA
25 library clones frequently lack the 5' end of the mRNA
coding sequences. For example, Figure 1 shows a common
procedure for the construction of hybrid gene cDNA
libraries. In Figure 1a, mRNA molecules with a
polyadenylated 3' end are annealed to an oligo[dT] primer
30 for first strand cDNA synthesis. Figure 1b shows a

consequence of the limitations of enzymatic in vitro cDNA synthesis: as reverse transcriptase moves along the mRNA to make the cDNA copy, it has a finite chance of "falling off" the mRNA at each step. The result is that each mRNA
5 has a low probability of being copied to a significant extent with a higher probability of being copied as middle to short cDNAs.

Another consequence of priming the first strand at the 3' end is that the cDNA will invariably contain the
10 non-coding untranslated region or UTR found in mRNAs. When making hybrid gene cDNA libraries, as with molecular interaction methods, this dictates that the vector sequences encoding the common peptide must be 5' to the cDNA itself. Indeed, all vectors intended for molecular
15 interaction studies are designed in this fashion. Figure 2 shows a typical example of such a vector for the current state of the art: The vector, known as JG4-5, is designed for two-hybrid screening of cDNA libraries using baker's yeast as host cells. The vector comprises an
20 origin of replication for maintenance in bacterial cells, an antibiotic resistance gene, for selection in same, a second origin of replication for yeast, and a nutritional gene for selection in same. The vector further comprises a transcriptional control start signal and stop signal
25 for expression of the hybrid gene, sequences encoding the common peptide including a translational start codon and a multiple cloning site or MCS for insertion of the cDNA.

A major shortcoming of vectors such as JG4-5 is illustrated in Edwards et al., (1997) Development 124:
30 3855-3864. Edwards et al. shows that amino acid 25 of

the protein Tube is necessary for it to interact with the protein Pelle. However, two-hybrid screens using hybrid proteins derived from traditional vectors with the common peptide on the 5' end fail to detect this interaction.

5 This failure likely occurs because few or none of the cDNA inserts contain enough of the 5' end of the Tube sequence to encode amino acid 25. The few cDNA inserts that do contain the 5' region likely also contain a stop codon located only 75 base pairs before the sequence
10 encoding amino acid 25 and thus result in a truncated hybrid protein that also lacks Tube amino acid 25. Absent a domain mapping study, current practical methods are unable to detect which two-hybrid interaction negatives are, like the Tube/Pelle interaction, actually
15 false negatives arising from insufficient presentation of a functional amino region of the test protein.

Only a few methods have been devised to overcome the above-mentioned paucity of cDNAs representing the 5' region of the mRNA. One approach, exemplified by Patent
20 No. 6,083,727 to Guegler, et. al (2000), involves enriching the library for clones containing the 5' end of mRNAs. A second approach is to purify cDNAs that are full-length; that is, those which are complete copies of the initial mRNA molecules, as in Patents No. 5,891,637
25 to Ruppert (1999) and 5,846,721 to Soares, et. al (1998). However, these methods are unusually demanding from a technical perspective and thus may prove prohibitively costly or time-consuming for widespread or high-throughput screens.

Figure 3a shows that an mRNA molecule with a polyadenylated 3' end can be reacted with synthetic oligonucleotides of random sequence which can anneal at various random locations along the length of the molecule. Figure 3b shows that enzymatic first strand synthesis performed with primers of this nature results in a higher probability of reaching the 5' end of the mRNA. This random-primed library therefore consists of a population of cDNAs differing in length at their 3' ends but adequately representing the 5' ends of the mRNAs.

Proper representation of the 5' ends of mRNAs is widely regarded as a decided advantage for the construction of cDNA libraries. However, using current systems for molecular interaction methods, which place the common peptide at the amino terminus of the hybrid protein, it is not possible to fully exploit such libraries in which the 5' ends are adequately represented because the 5' cDNA region, including the UTR, would be placed at the 3' end of the sequence encoding the common peptide. Because of positional effects within the hybrid protein, even though the 5' region is expressed, it may not function simply because it is located at the wrong end of the hybrid protein.

A few vectors do currently exist which place the common peptide at the carboxyl terminus of the hybrid protein. In most cases, however, these vectors are intended for the expression of a known gene or gene fragment. Accordingly, they require knowledge of the nucleotide sequence of the gene or fragment for the design of cloning strategies that will result in proper

expression. This is clearly not feasible for libraries composed of thousands of unknown sequences.

Other vectors of this type have been designed for library screens, although in these instances either the
5 library or the screen is limited to a narrow range of applications. For example, phage display libraries sometimes encode the common peptide (a bacteriophage coat protein) at the carboxyl terminus, but said libraries are collections of small, synthetic oligonucleotides, all of
10 which are present in equal proportions. This is not the case with cDNAs.

As another example, U.S. Patent No. 6,103,472 to Thukral (2000), describes construction of a hybrid gene cDNA library with the cDNA encoded peptide at the amino
15 terminus of the hybrid protein, but the library is specifically useful for detecting peptides with a single function, the ability to be secreted from within the cell. In order to be useful, hybrid gene cDNA libraries for molecular interaction methods must not be constrained
20 by the nature of the insert. Further, since they are intended for use with various "baits", each of which is expected to have a unique function, hybrid gene cDNA libraries for molecular interaction studies cannot be constrained by the function of the cDNA-encoded peptide.

25 Current cDNA vectors for molecular interaction methods, such as JG4-5, invariably place the common peptide at the amino-terminus of the hybrid protein. This places several constraints on the utility of the vectors and hybrid proteins during molecular interaction

screening. Several significant constraints are as follows:

- (a) The common peptide is expressed in the cells regardless of whether a cDNA insert is present in the vector. With certain methods of detection this may give rise to undesirable background signal.
- (b) The common peptide determines the reading frame for the entire hybrid gene. Due to the random nature of the 5' end of cDNAs, discrepancies in reading frame result in the production of hybrid peptides with unwanted, out-of-natural frame structures. This occurs in two thirds of all the clones in a library. Some are invariably detected as false positives.
- (c) cDNAs that are copies of non-coding RNAs produce irrelevant hybrid peptides. As an example, ribosomal RNA or rRNA, which does not encode any proteins, is by far the most abundant RNA species in any cell. Consequently, even the most conscientiously prepared cDNA libraries can be expected to contain rRNA clones. With current vectors, these clones express rRNA hybrid proteins which can be detected as false positives. This occurs because the start codon is provided before the common peptide, so the lack of a start codon in most rRNA in no way prevents its expression.
- (d) A substantial number of the already underrepresented fraction of cDNAs that do include the 5' end of the corresponding mRNA contain an additional non-coding untranslated region or UTR found at 5' end of the mRNAs. This precludes the possibility of generating productive

hybrid proteins if the UTR separates the common peptide from the protein-coding region of the cDNA.

(e) In order to be functional, each protein must fold in a specific three-dimensional configuration. For
5 individual segments or domains of proteins this is often dependent on the context in which they are found. For example, a protein modified so that its amino-terminal and carboxy-terminal portions are reversed will most often lose its function. Molecular interaction methods
10 rely on the maintenance of domain function in the hybrid protein. Since current vectors for molecular interaction methods invariably place the cDNA downstream of the common peptide sequences, cDNA-derived protein domains that are intended to be amino-terminal are placed at the
15 carboxyl-terminus of the hybrid protein. This can abolish function and result in false negative results.

SUMMARY OF THE INVENTION

The invention includes a hybrid gene cDNA library
20 comprising a series of vectors, each vector comprising a DNA molecule having at least one selectable marker sequence and a sequence encoding a hybrid protein region. The hybrid protein region comprises a regulatable sequence, a multiple cloning site that does not encode a
25 translational termination sequence or a start codon placed immediately 3' to the regulatable DNA sequence, a sequence encoding at least one common peptide and not containing a translation initiation codon placed 3' to the multiple cloning site. Each vector of the library
30 additionally comprises a single cDNA molecule inserted at

the multiple cloning site. Each of these single cDNA molecules is obtained from a cDNA population generated using random primers. The vector is preferably a plasmid.

5 The vector may additionally comprise one or more origins of replication active in bacteria cells as well as one or more origins of replication active in yeast cells. The hybrid protein region may additionally comprise a DNA molecule which encodes a transcriptional
10 termination sequence placed immediately 3' to the DNA molecule encoding at least one common peptide.

 In a more preferred embodiment, the regulatable sequence is the rat Glucocorticoid Response Element. In another preferred embodiment it may be an Estrogen
15 Response Element. The common peptide is preferably encoded by a DNA molecule comprising sequences encoding all or portions of the GAL4 yeast transcriptional activator and six successive histidine residues or, alternatively, a nuclear localization sequence from the
20 SV40 virus.

 In one particular embodiment, the common peptide is encoded by a DNA molecule comprising sequences encoding an immunological epitope from adenoviral hemagglutinin.

 The vector may also include one or more origins of
25 replication active in yeast cells and one or more origins of replication active in bacterial cells. At least one yeast origin of replication is derived from the natural 2-micron yeast plasmid. The selectable marker sequences may be the bacterial ampicillin resistance gene and the
30 yeast TRP 1 nutritional auxotrophy gene or,

alternatively, the bacterial kanamycin resistance gene and the yeast URA3 nutritional auxotrophy gene. The preferred transcriptional termination sequence is derived from the yeast ADH 1 gene.

5 The present invention also includes a method of producing hybrid proteins. In this method, first a purified sample of a vector comprising a DNA molecule with at least one selectable marker sequence and a sequence encoding a hybrid protein region is provided.

10 The hybrid protein region ideally comprises a regulatable DNA sequence, a multiple cloning site that does not encode a translational termination sequence placed immediately 3' to the regulatable DNA sequence, and a DNA sequence encoding at least one common peptide and not

15 containing a translation initiation codon placed 3' to the multiple cloning site. Next, a mRNA template population of interest is isolated and a cDNA population is synthesized from the mRNA template population using random sequence oligonucleotide primers. This synthesis

20 is preferably conducted using PCR. Cloning linkers may then be added to the cDNA population and it may be inserted into the vector, which has been cleaved at the multiple cloning site, thus creating a hybrid gene cDNA library. This library may then be expanded by

25 transforming bacterial cells with the library and selecting then growing transformed cells. The library may then be purified from the transformed cells. In a preferred embodiment, the bacterial cells transformed with the hybrid gene cDNA library are *E. coli* cells.

The invention additionally includes a method of performing a yeast two-hybrid assay. First a hybrid gene cDNA library of the present invention is provided in which the common peptide includes a DNA activation
5 domain. The library is then used to transform yeast cells which contain another hybrid protein. This other hybrid protein includes a DNA binding polypeptide and a bait polypeptide as well as a DNA molecule with a sequence to which the DNA binding polypeptide may bind.
10 In the vicinity of this sequence the DNA molecule also contains a sequence activatable by the DNA activation domain of the cDNA library hybrid protein. The DNA molecule additionally includes a reporter sequence that may be activated if the DNA activation domain is brought
15 into proximity with the activatable sequence. Transformed cells are then selected and an assay may be performed to detect activation of the reporter sequence. Activation is indicative that the polypeptide encoded by the particular cDNA insert in a given cell is capable of
20 interaction with the bait polypeptide.

In a preferred embodiment of this method, the DNA activation domain is derived from the yeast the GAL 4 activation domain, and the reporter sequence is derived from the yeast GAL 4 gene. Additionally, the hybrid gene
25 cDNA library vector preferably includes a TRP 1 nutritional auxotrophy gene as the selectable marker sequence and the yeast cells are trp 1 mutant yeast cells. Alternatively, the vector may include a URA 3 nutritional auxotrophy gene as the selectable marker

sequence and the yeast cells may be ura 3 mutant yeast cells.

In still another preferred embodiment, the common peptide may additionally comprise a nuclear localization
5 sequence which may be the nuclear localization sequence from the SV40 virus.

Accordingly, several objects and advantages of the present invention are:

- (a) to eliminate the potential background and false
10 positives resulting from vectors that lack a cDNA insert.
- (b) to eliminate hybrid proteins derived from reading frame shifts in the cDNA-derived protein segment of the hybrid-protein relative to the common peptide.
- (c) to eliminate hybrid proteins resulting from the
15 presence of cDNAs from noncoding RNAs, such as mRNAs.
- (d) to avoid the disruption of reading frame continuity by the presence of 5' UTRs in the cDNA.
- (e) to place the amino-terminal peptide domains from the cDNA library at the amino-terminus of the hybrid protein.

20 Further objects and advantages are to provide a method for the construction of hybrid gene cDNA libraries that is simple and efficient, yet allows the cloning of cDNAs that represent the 5' region of the starting mRNAs, and that is not constrained either by the nature of the
25 inserts or by the function of the peptides encoded therein. Still further objects and advantages will become apparent from a consideration of the Detailed Description and Drawings. It will be understood by one skilled in the art that every embodiment of the present invention
30 need not necessarily fulfill all objects and advantages

of the overall invention. A more detailed understanding of the invention may be had through reference to the Detailed Description.

5 BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 illustrates the method and results of oligo[dT]-primed cDNA synthesis, with a population of cDNAs. Figure 1a shows the oligo[dT]-primer annealed to the poly-A tail of the RNA. Figure 1b shows the various
10 lengths of cDNA molecules obtained before reverse transcriptase falls off the RNA. As the three example cDNAs indicate, this method is biased towards representation of the 3' end of the RNA.

Figure 2 is a diagram of JG4-5, a current state of the art vector for the construction of hybrid gene cDNA
15 libraries, with the DNA sequences encoding the common peptide 5' to the multiple cloning site.

Figure 3 illustrates the method and results of random-primed cDNA synthesis with a population of cDNAs.
20 Figure 3a shows the random primers annealed to random sequence at various locations along the RNA. Figure 3b shows various lengths of cDNA molecules obtained before reverse transcriptase falls off the RNA. As the three example cDNAs indicate, this method is not biased towards
25 any portion of the RNA so the 5' end is represented as well as other regions.

Figure 4 is a diagram of one embodiment of the present invention, with the DNA sequences encoding the common peptide 3' to the multiple cloning site.

30

DETAILED DESCRIPTION OF THE INVENTION

The present invention provides hybrid gene cDNA libraries. It also provides methods for using such
5 libraries to allow the cloning and detection, as hybrid genes or hybrid proteins, of sequences that encode functional amino-terminal peptides from the 5' end of mRNAs.

The vectors of the present invention used in
10 construction of the hybrid cDNA libraries generally have one or more origin(s) of replication to allow for replication and/or maintenance in yeast or bacteria cells, if the vector is to be used in such cells, a selectable marker sequence allowing selection of cells
15 comprising the vector, and a sequence encoding a hybrid protein region. The sequence encoding a hybrid protein region comprises a regulatable DNA sequence, a multiple cloning site (MCS) placed immediately downstream, or 3' to the regulatable DNA sequence that does not contain
20 translational termination sequences, and sequences encoding at least one common peptide, but not encoding a translation initiation codon located downstream, or 3' to the MCS. Immediately 3' or downstream of the common protein sequence a transcriptional termination sequence
25 may be included to ensure proper termination and processing of the hybrid gene mRNA.

In a preferred embodiment, the regulatable DNA sequence in the hybrid protein region is the
Glucocorticoid Response Element (GRE) from rat and the
30 common peptide is encoded by a fusion of sequences

derived from the DNA binding domain of the yeast transcriptional activator GAL4 and sequences encoding six successive histidine residues. The GAL 4 sequences make the hybrid fusion protein useful in yeast two-hybrid
5 assays and the histidine sequences are useful for affinity purification of the hybrid protein.

Additionally, the vector preferably contains both a bacterial origin of replication and a yeast origin of replication, in particular, an origin of replication
10 derived from the natural 2-micron yeast plasmid. The vector also comprises a bacterial ampicillin resistance gene for propagation and selection in *E. coli*, and the yeast TRP 1 nutritional auxotrophy gene for propagation and selection in *trp1* mutant yeast. This preferred
15 embodiment is depicted in Figure 4.

In other preferred embodiments, the selectable marker is a bacterial antibiotic resistance gene conferring resistance to kanamycin and the yeast nutritional auxotrophy gene is URA3, which confers upon
20 *ura3* mutant yeast the ability to grow in the absence of supplemental uracil. The nucleotide sequences encoding a common peptide may be derived from the GAL4 activation domain fused to a nuclear localization sequence from the virus SV40, also for use in a yeast two-hybrid assay.
25 The common peptide sequences may also be sequences encoding an immunological epitope from adenoviral hemagglutinin. The DNA regulatory sequence may be an Estrogen Response Element.

There are various possibilities with regard to the
30 disposition of certain elements which constitute the

vector, as their relative placement and orientation do not affect its performance. This applies to both origins of replication and both selectable marker genes as to their placement relative to each other, and to their
5 collective placement on either side of hybrid protein region. Only the hybrid protein region is intended to have the internal disposition of elements described above.

Other alternative embodiments result from the
10 substitution of one or more of any of the elements by other similar elements which may serve a similarly useful function. For example, different origins of replication and/or selectable markers suitable for other host cells may be useful as may different transcriptional initiation
15 and/or termination sequences, multiple cloning sites designed for specific applications, and sequences encoding common peptides with different detectable functions. These functions may be suitable for molecular interaction methods but are not limited to these methods,
20 and alternative embodiments of the present invention can be designed to suit other specific applications of hybrid gene libraries.

In the hybrid gene cDNA library, multiple copies of the vector are present and each vector contains a cDNA
25 insert at the multiple cloning site. The hybrid gene cDNA library may be generated using the vector described above and any insertion techniques known to the art. However, the cDNA molecules which are inserted into the vector to form the cDNA library are preferably obtained
30 using random primers as described below.

The method of preparing the hybrid gene cDNA library of the present invention may comprise a number of steps, each of which can be readily performed in any laboratory with the equipment and skills in the art. Specifically,
5 for the embodiment depicted in Figure 4 and similar embodiments the steps include:

- (a) Propagation of the vector in *E. coli* cells, and purification of vector DNA;
- (b) Isolation or acquisition of the mRNA template
10 population of interest, and synthesis of a cDNA population from the template using random sequence oligonucleotide primers;
- (c) Addition of cloning linkers to the cDNA population and insertion of the cDNA into the appropriately cleaved
15 vector (e.g. cleaved at the MCS);
- (d) Transformation of *Escherichia coli* cells with the hybrid gene cDNA library, and propagation and purification of same;
- (e) Transformation of yeast cells, selection for
20 transformed cells and performance of yeast two-hybrid screen.
- (f) Identification, purification and propagation of positive clones.
- (g) Affinity purification of hybrid protein via the 6X-
25 Histidine tag.

The precise details of each of the above steps can be modified to suit individual applications and embodiments of the invention.

As this description makes clear, the present
30 invention avoids several of the shortcomings of previous

vectors. First, the vector of the invention will not express the common peptide unless it contains a cDNA insert. Because the vector relies on the cDNA's own start codon and not one placed before the common peptide
5 or before the cDNA insert, as in the prior art, no common peptide may be produced by any vector that does not contain a cDNA insert comprising a start codon. Therefore, the vector of the present invention is incapable of producing the common peptide unless it is
10 part of a hybrid protein, thereby avoiding background signal in many types of assays.

Second, hybrid proteins cannot contain an out of frame polypeptide encoded by the cDNA insert because the insert itself comprises the start codon and determines
15 the reading frame. In many previous vectors the cDNA may be translated in frame with the common peptide, but often out of its natural reading frame. These out-of-natural frame regions may interact with molecules with which the natural, in-frame peptide will not interact, thus giving
20 false positives in a molecular interaction screening. In the present invention, the cDNA-generated polypeptide is always in frame. The common peptide may be out of frame in two thirds of the hybrid proteins, but, because the sequence of the common peptide is known, the amino acid
25 sequence of out-of-frame common peptides may be determined. If the out-of-frame common peptides are likely to cause false results or otherwise interfere with an assay using the hybrid proteins, steps may be taken to avoid this by using a different common peptide or to
30 detect false results.

Third, with previously known vectors, hybrid proteins comprising a common peptide and a peptide encoded by ribosomal RNA are common. These peptides may produce high background levels in many assays or even
5 false positives. This problem is avoided in the present invention because it is very unlikely that a vector with a rRNA-derived cDNA will be able to produce a hybrid protein comprising the common peptide. Most rRNA derived cDNAs will lack a start codon. Additionally, rRNA is
10 replete with stop codons, so it is unlikely translation will progress far enough to reach the common peptide sequence.

Fourth, most previous vectors for use with a hybrid gene cDNA library seriously underrepresent the 5' end of
15 RNAs. Essentially, even if cDNA generated using random primers so the 5' ends are represented, these 5' ends often contain a portion of the 5' untranslated region. As shown in Edwards et al. and described more fully in the Background, this untranslated region may encode stop
20 codons or other sequences that interfere with translation or folding or stability of the translated protein. Using conventional vectors with the cDNA placed 3' relative to the common peptide DNA, the 5' untranslated region generally interferes with translation and precludes
25 representation of the 5' ends of RNAs. Thus interactions, such as those between Tube and Pelle which are virtually undetectable with present techniques may be readily observed using a hybrid gene cDNA library of the present invention.

In the present invention, the 5' UTR is of no relevance to translation of a complete hybrid protein because it is 5' relative to the start codon.

Essentially, by placing the 5' UTR in a more natural
5 position, the present invention abrogates its ability to interfere with translation of the hybrid protein.

Fifth, the 5' end of RNA usually encodes for the amino terminus of a protein. However, in previous vectors this normally amino terminal region is placed on
10 the carboxy terminus of the hybrid protein. This placement may interfere with the three-dimensional structure and domain function of the peptide encoded by the 5' RNA region, rendering it unable to interact with other proteins in a normal manner. As a result, many
15 false negatives may be obtained if such hybrid proteins are used in molecular interaction studies. The present invention avoids this problem by placing the 5' end of the RNA via the cDNA in the 5' portion of the hybrid gene. Therefore amino terminal domains are located in
20 the amino terminus of the hybrid protein and are more likely to retain their normal three-dimensional structures and functions.

The present invention has application in many circumstances. One important application is in any assay
25 or study in which one wishes to detect all of a particular type of molecular interaction, such as all proteins in a cell capable of interacting with another protein. To avoid positional effects resulting from the 3' end of the RNA being placed at the 5' end of the
30 hybrid protein, the vector library of the present

invention may be combined with a more traditional vector library. Situations in which this method is desirable to detect all interactions and ways in which multiple types of hybrid gene libraries may be combined in studies will
5 be apparent to one skilled in the art.

In order to facilitate a more complete understanding of the invention, a number of Examples are provided below. However, the scope of the invention is not limited to specific embodiments disclosed in these
10 Examples, which are for purposes of illustration only. Some alternative embodiments are described above and others will be apparent to those skilled in the art.

EXAMPLES

15

Example 1: GAL4/Histidine Common Peptide Hybrid Gene Library Vector

One preferred embodiment of the vector of the
20 present invention is depicted in Figure 4. The vector is a circular DNA molecule comprising a bacterial origin of replication and the bacterial ampicillin resistance gene Bla for propagation and manipulation in *Escherichia coli* cells. The vector further comprises the yeast TRP1
25 nutritional auxotrophy gene for vector selection in trp1 mutant yeast and a yeast origin of replication derived from the natural 2-micron yeast plasmid. Expression of the hybrid protein is driven by a regulatable DNA
sequence, related to the Glucocorticoid Response Element
30 GRE from rat. A multiple cloning site for ligation of the

cDNA inserts is placed immediately adjacent to and in a 3' or downstream orientation to the GRE. The multiple cloning site is designed to not contain the translational termination sequences TAA, TAG or TGA in any reading
5 frame. Adjacent to and 3' or downstream of the multiple cloning site are sequences encoding the common peptide which is itself a fusion of sequences derived from the DNA binding domain of the yeast transcriptional activator GAL4 and sequences encoding six successive histidine
10 residues for affinity purification of the hybrid protein. Notably, the sequences in the common peptide lack a translational initiation codon. Finally, adjacent and in a 3' orientation or downstream of the common peptide sequences is a transcriptional terminator derived from
15 the yeast ADH1 gene to ensure proper termination of transcription and processing of the hybrid gene mRNA. The region comprising the DNA regulatory element, MCS, common peptide, and transcriptional terminator is known as the hybrid protein region.

20

Example 2: Method of Producing and Purifying Hybrid Protein Products

A method of using the vector described in Example 1
25 consists of a number of steps, each of which can be readily performed in any laboratory with the equipment and skills in the art. Specifically, for the embodiment depicted in Figure 4 and described in Example 1 the steps are:

- (a) Propagation of the vector in *Escherichia coli* cells, and purification of vector DNA.
- (b) Isolation or acquisition of the mRNA template population of interest, and synthesis of a cDNA
- 5 population using random sequence oligonucleotide primers.
- (c) Addition of cloning linkers to the cDNA population and insertion of a single molecule of the cDNA into an appropriately cleaved vector. This occurs in multiple vectors simultaneously so that nearly all of the cDNA
- 10 molecules are each inserted into a separate vector.
- (d) Transformation of *Escherichia coli* cells with the hybrid gene cDNA library, and propagation and purification of same.
- (e) Transformation of yeast cells and performance of
- 15 yeast two-hybrid screen.
- (f) Identification, purification and propagation of positive clones.
- (g) Affinity purification of hybrid protein via the 6X-Histidine tag.

20

Example 3: Hybrid Gene Library Screen

A cDNA population derived from of a cell known to express Tube has been prepared and inserted into the JG4-5 vector of Figure 2. The common peptide is a

25 polypeptide derived from the GAL 4 activation domain, but it may also be a different transcriptional activator. The resulting hybrid gene cDNA library is then be used in a standard yeast two-hybrid assay by transforming yeast in which a hybrid protein comprising the Pelle bait

polypeptide and a DNA binding polypeptide is also present. The reporter sequence in such an assay is derived from the yeast β -gal gene. The cDNA sequences of interacting hybrid proteins which activate the reporter
5 sequence and yield positive results in the assay were then analyzed. As shown in previous studies in Edwards et al., no positives are observed.

The same cDNA population has also been placed in the vector of this invention, shown in Figure 4, in which the
10 common peptide is the same as in the JG4-5 vector, and subjected to the same two-hybrid assay. In this assay true positives are observed. Analysis confirms that they represent vectors comprising the 5' RNA sequence of Tube, which encodes amino acid 25. Thus, the identical two-
15 hybrid assay using the vector of this invention with a cDNA population generated according to the invention uncover an interaction not detected using a conventional vector and a polyA-generated cDNA population.
